

# CONTROL OF SYSTEMS BY PARALLEL ACTUATORS

STEPHEN MONTGOMERY-SMITH

**ABSTRACT.** We describe a particular control method for a system controlled by several actuators with the same control constants. We show under certain assumptions that the control constants for the whole system can be obtained immediately from the control constants for a single actuator, and that no gain scheduling is required.

## 1. INTRODUCTION

In this paper, we describe a system whose state, which we will call the *end effector position*, is given by an element of a differential manifold  $\eta \in \mathcal{M}$ . We suppose that the end effector position is determined by the *values* of  $n$  actuators:

$$\ell = (\ell_1, \ell_2, \dots, \ell_n) \in \mathbb{R}^n. \quad (1)$$

We write  $L : \mathcal{M} \rightarrow \mathbb{R}^n$  for the function which maps the end effector position to the actuator values. Note that we can allow the problem to be over-constrained, that is,  $n$  can be bigger or equal to the dimension of  $\mathcal{M}$ . Note that the elements of  $\mathcal{M}$  are generalized positions in the sense of the Euler-Lagrange formalism [1].

Examples of these are cable-driven parallel robots, consisting of a fixed rigid frame, and a floating rigid body called the end effector. The end effector is manipulated via eight cables attached to actuators. Each actuator is clamped to the fixed frame. The value,  $\ell_k$ , of the  $k$ th actuator is the length of cable issued by the actuator. The manifold  $\mathcal{M}$  is the six dimensional space of poses, that is, positions with orientations. See [2, 3, 10] for an introduction to parallel robots. See [8, 9] for information about cable-driven parallel robots. The algorithm described in this paper was tested upon a cable-driven parallel robot built by the NASA Johnson Space Center, which we describe in another paper [7].

---

This is a preprint of a paper intended for submission to a journal. Because changes may be made before formal publication, this preprint is made available with the understanding that it is not to be cited or reproduced without permission of the author.

Date: Feb 9, 2022.

We assume that the only measurements we can take are the values of the actuators, and that the only method of control is to command a force at each actuator, which converts into a force on the end effector. We assume that once the end effector force is known, one can determine the trajectory of the end effector via a frictionless, quadratic Hamiltonian system. The force is a generalized force obeying the principle of virtual work, and we will call it the *end effector force*.

The method of control is to calculate the end effector position using the actuator values. Then, from the difference of the actual end effector position from the requested end effector position, is calculated the required acceleration of the end effector. From this is calculated the required end effector force. Finally, we find the actuator forces to effect this.

Our main contribution is to show that the control constants for computing the required acceleration of the end effector are the same as the control constants used to control a single actuator, making it easier to determine the control method. This result requires two things. First that the actuator response is linear. This would be violated if, for example, if there is significant non-linear friction. Second, it requires that the each actuator by itself can be controlled by the same linear controller. For example, with the cable-driven parallel robot, if there is significant flexing or stretching of cables, this would require a different control method for each actuator because the orientations and/or lengths of the cables aren't necessarily identical.

Since the control constants can be found by considering a controller for a single actuator, then the same control constants can be used irrespective of the end effector position, that is, no gain scheduling is required. Thus the formula for resonant frequencies can also be calculated from the resonant frequencies of a single actuator.

We believe the methods and results in Sections 4 and 5, where we show that the control constants come from those described in Section 3, are new. But it is possible that these methods were developed in a completely different context, and that the author is simply unaware of them.

## 2. MATHEMATICAL DESCRIPTION OF THE SYSTEM

Denote by  $T_\eta \mathcal{M}$  the tangent space of  $\mathcal{M}$  at  $\eta$ , by  $T\mathcal{M} = \bigcup_{\eta \in \mathcal{M}} T_\eta \mathcal{M}$  the whole tangent space, and by

$T^*\mathcal{M} = \bigcup_{\eta \in \mathcal{M}} T_\eta^*\mathcal{M}$  the cotangent space. See [6] for information on manifolds.

Given a position that is a function of time,  $\eta(t)$ , we have its velocity and acceleration which are functions of time taking their values in  $T\mathcal{M}$  given by

$$\varphi = \dot{\eta}, \quad \alpha = \dot{\varphi}. \quad (2)$$

We define the linear operator  $\Lambda_\eta : T_\eta\mathcal{M} \rightarrow \mathbb{R}^n$  by the directional derivative, which in local coordinates is

$$\Lambda_\eta \theta = \theta \cdot \frac{d\mathbf{L}(\eta)}{d\eta}. \quad (3)$$

Often we simply write  $\Lambda$  for  $\Lambda_\eta$  when there is no confusion.

Then, from the velocity  $\varphi$ , we can calculate the rate of change of the actuator values:

$$\dot{\ell} = \Lambda_\eta \varphi. \quad (4)$$

We suppose that there is a linear operator  $\mathbf{T} = \mathbf{T}_\eta : \mathbb{R}^n \rightarrow T^*\mathcal{M}$ , which converts actuator forces  $\mathbf{f} = (f_1, f_2, \dots, f_n)$  to the end effector force  $\tau$ :

$$\tau = \mathbf{T}_\eta \mathbf{f}. \quad (5)$$

By the principle of virtual work, we have

$$\varphi \cdot \mathbf{T}_\eta \mathbf{f} = \dot{\ell} \cdot \mathbf{f} = \Lambda_\eta \varphi \cdot \mathbf{f}. \quad (6)$$

Hence

$$\mathbf{T}_\eta = \Lambda_\eta^T. \quad (7)$$

Next we describe the equations of motion. Suppose that the system is given by a Lagrangian

$$l(\eta, \varphi) = \frac{1}{2} \mathbf{M}_\eta(\varphi, \varphi) - v(\eta), \quad (8)$$

where  $\mathbf{M}_\eta = \mathbf{M}$  is a positive definite bilinear operator on  $T_\eta\mathcal{M}$ . This includes kinetic energy of the actuators

$$\frac{1}{2} m_0 |\dot{\ell}|^2, \quad (9)$$

where  $m_0$  is the effective mass of the each actuator (the notion of ‘effective’ is explained in Section 3 below). In local coordinates we can describe  $\Lambda$  and  $\mathbf{M}$  as matrices, then the kinetic energy of the actuators is given by

$$\frac{1}{2} m_0 \varphi^T \Lambda^T \Lambda \varphi, \quad (10)$$

and so we must have that the matrix

$$\mathbf{M} - m_0 \Lambda^T \Lambda \quad (11)$$

is positive semi-definite.

Solving the Euler-Lagrange equations [1], we obtain the equations of motion

$$\tau = \mathbf{M}\alpha + \mu(\eta), \quad (12)$$

where in local coordinates

$$\mu(\eta) = \varphi \cdot \frac{\partial \mathbf{M}_\eta}{\partial \eta}(\varphi, \cdot) - \frac{\partial}{\partial \eta} v(\eta). \quad (13)$$

We define the *no-load forces* to be the actuator forces if the actuators are not attached to the system, that is, the Lagrangian is given simply by equation (9):

$$\mathbf{f}_0 = m_0 \ddot{\ell}. \quad (14)$$

Thus differentiating equation (4), we obtain (in local coordinates)

$$\mathbf{f}_0 = m_0 \Lambda_\eta \alpha + m_0 \varphi \cdot \frac{d\Lambda_\eta}{d\eta} \varphi. \quad (15)$$

For the example of the cable-driven parallel robot, the cable tensions are given by

$$\text{cable tensions} = \mathbf{f}_0 - \mathbf{f}. \quad (16)$$

Next, we need inverse functions to  $\mathbf{L}$  and  $\mathbf{T}$ , which we call  $\mathbf{Y}$  and  $\mathbf{F}$ .

We define the *set of admissible actuator values*,  $\mathcal{L} \subset \mathbb{R}^n$ , to be the range of the function  $\mathbf{L}$ . We suppose that we have a *forward kinematics* function,  $\mathbf{Y} : \mathcal{L} \rightarrow \mathcal{M}$ , which is a left inverse to  $\mathbf{L}$ . Because of possible measurement errors,  $\mathbf{Y}$  should produce decent answers even if the actuator values are merely close to  $\mathcal{L}$ . For example, this could be implemented using the Newton-Raphson Method.

For the inverse function of  $\mathbf{T}$ , we need some more definitions. Given  $\mathbf{f}_b, \mathbf{f}_0 \in \mathbb{R}^n$ , we suppose that we have a predefined set  $\mathcal{C}_{\mathbf{f}_b, \mathbf{f}_0} \subset \mathbb{R}^n$ . Here  $\mathbf{f}_b$  is the command force required to overcome actuator resistance such as back-EMF,  $\mathbf{f}_0$  is the no-load actuator forces, and  $\mathcal{C}_{\mathbf{f}_b, \mathbf{f}_0}$  is the set of those  $\mathbf{f}$  such that it is permissible to command forces  $\mathbf{f} + \mathbf{f}_b$  to the actuators.

Typically this is a convex set defined by a finite number of linear constraints. For the example of cable-driven parallel robots, we might say  $\mathbf{f} \in \mathcal{C}_{\mathbf{f}_b, \mathbf{f}_0}$  if and only if the tensions in the cables,  $\mathbf{f}_0 - \mathbf{f}$ , is never below a given predefined value, and the command forces  $\pm(\mathbf{f} + \mathbf{f}_b)$  don’t exceed the actuator hardware limits.

Then we define the *wrench set* to be the set of achievable forces:

$$\mathcal{W} = \{(\tau, \mathbf{f}_b, \mathbf{f}_0) \in T^*\mathcal{M} \times \mathbb{R}^n \times \mathbb{R}^n : \exists \mathbf{f} \in \mathcal{C}_{\mathbf{f}_b, \mathbf{f}_0} \text{ such that } \mathbf{T}\mathbf{f} = \tau\}. \quad (17)$$

We suppose that we have a function  $\mathbf{F} : \mathcal{W} \times \mathbb{R}^n \times \mathbb{R}^n \rightarrow \mathbb{R}^n$  that provides a right inverse to the map defined by  $\mathbf{T}$  in the following manner:

$$\mathbf{T}(\mathbf{F}(\tau, \mathbf{f}_b, \mathbf{f}_0)) = \tau, \quad (18)$$

such that

$$\mathbf{F}(\tau, \mathbf{f}_b, \mathbf{f}_0) \in \mathcal{C}_{\mathbf{f}_b, \mathbf{f}_0}. \quad (19)$$

Because there are more actuators than the number of degrees of freedom (that is, the dimension of  $\mathcal{M}$ ,

computing the actuator forces in the last step is an over-constrained problem. For the example of cable-driven cable robots, there are many approaches in the literature [4, 5, 8].

Finally we need a way to approximate the difference between two end effector positions by an element of the tangent space. That is, there is a function  $\Delta : \mathcal{M} \times \mathcal{M} \rightarrow T\mathcal{M}$  such that  $\Delta(\eta_1, \eta_2)$  is in  $T_{\eta_1}\mathcal{M}$ , so that with respect to a ‘reasonable’ coordinate system about  $\eta_1$  that

$$\eta_2 \approx \eta_1 + \Delta(\eta_1, \eta_2). \quad (20)$$

For example, if  $\mathcal{M}$  is a Riemannian manifold, we could define it as the direction of a geodesic from  $\eta_1$  to  $\eta_2$ . If  $\mathcal{M}$  is a Lie group, we could define it as the direction of a one parameter subgroup from  $\eta_1$  to  $\eta_2$ .

### 3. CONTROL OF A SINGLE ACTUATOR

Let  $\ell$  denote actuator value, let  $f_c$  be the command force given to a single actuator, and  $f$  be the actual force supplied by this actuator.

Each actuator has an *effective* no-load mass  $m_0$ , which is the ratio  $f/\ddot{\ell}$  when there is no load placed upon the actuator.

For the remainder of this section, we suppose that the actuator is carrying a passive load. We denote by  $m$  to be the effective mass of the actuator with this load. Thus no load corresponds to  $m = m_0$ , and we always have  $m \geq m_0$ . If the actuator is clamped so that it cannot move, this corresponds to  $m = \infty$ , which is a mathematical idealization representing when the passive load is very large.

For the purpose of making the analogue of these equations and the system controller equations clearer, we shall replace the actuator actual and command forces by actual and command accelerations

$$a = \frac{f}{m} = \ddot{\ell}, \quad (21)$$

$$a_c = \frac{f_c}{m}. \quad (22)$$

We look for a controller such that, given an actuator value  $\ell_r$ , attempts to create a command acceleration  $a_c$  such that the actual actuator value,  $\ell$ , is close to  $\ell_r$ .

First we describe an *open-loop* controller:

$$f_c = m\ddot{\ell}_r + k_0\dot{\ell}_r, \quad (23)$$

or

$$a_c = \ddot{\ell}_r + \frac{k_0}{m}\dot{\ell}_r. \quad (24)$$

We call  $k_0$  the back-EMF constant, since for electric motors this is a likely source of this term. This controller fails badly if there is any drift or noise in the system, because it makes no attempt to correct for error.

Next, suppose we also have a good *homogeneous closed-loop* controller. Denote the vector containing all time derivatives of order less than  $l$  of  $\ell$  by

$$\boldsymbol{\ell} = [\ell, \dot{\ell}, \ddot{\ell}, \dots, \ell^{(l-1)}]^T. \quad (25)$$

The controller is defined by appropriately sized constant matrices  $\mathbf{A}$ ,  $\mathbf{B}$ ,  $\mathbf{C}$ , and  $\mathbf{D}$  as:

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\boldsymbol{\ell} \quad (26)$$

$$a_c = \mathbf{C}\mathbf{x} + \mathbf{D}\boldsymbol{\ell}. \quad (27)$$

By a good homogeneous closed-loop controller, we mean that if this is used to control the passively loaded actuator, then  $\ell$  converges to 0 in a manner that is expeditious enough for our application.

Note that if cable stretching or sagging plays a significant role in the cable-driven parallel robot, then this should be able to control a single actuator with a cable with similar stretching or sagging characteristics attached.

The results of this paper don’t depend upon what definition of ‘good’ we use. Our assertion is that the parallel actuator driven robot controller behaves as well as the single actuator controller.

We combine the open-loop and homogeneous closed-loop controller to obtain a good *closed-loop feed-forward* controller, that is, given a requested actuator value  $\ell_r$ , and its vector of derivatives

$$\boldsymbol{\ell}_r = [\ell_r, \dot{\ell}_r, \ddot{\ell}_r, \dots, \ell_r^{(l-1)}]^T, \quad (28)$$

we find the command acceleration  $a_c$  such that  $\ell$  converges to  $\ell_r$  in an expeditious manner. This can be created by applying the homogeneous closed-loop controller to

$$\ell_d = \ell - \ell_r \quad (29)$$

$$\boldsymbol{\ell}_d = \boldsymbol{\ell} - \boldsymbol{\ell}_r \quad (30)$$

to obtain

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{B}\boldsymbol{\ell}_d \quad (31)$$

$$a_c = \ddot{\ell}_r + \frac{k_0}{m}\dot{\ell}_r + \mathbf{C}\mathbf{x} + \mathbf{D}\boldsymbol{\ell}_d. \quad (32)$$

### 4. THE CONTROLLER FOR THE SYSTEM BY PARALLEL ACTUATORS

For the controller, we introduce the state vector  $\boldsymbol{\xi}$ , which is a vector of elements from the tangent space, with the same number of components as the state vector  $\mathbf{x}$  described in equation (26). We denote a matrix multiplied by a vector of elements from the

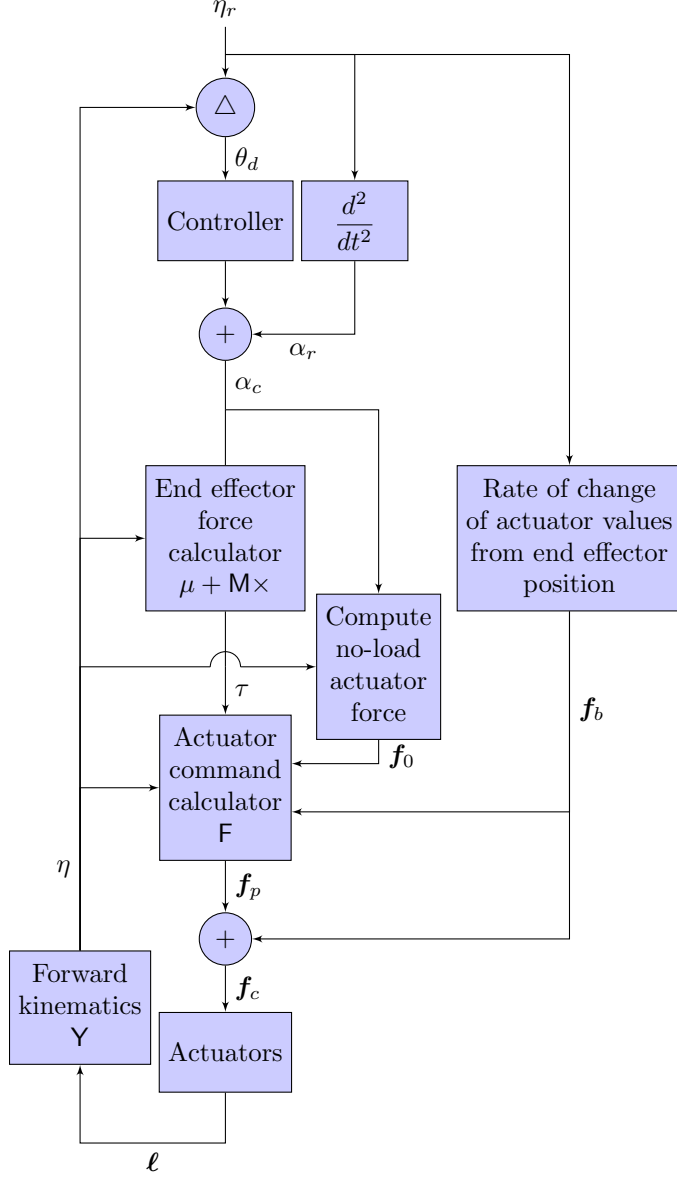

FIGURE 1. Block diagram of the controller for the robot driven by parallel actuators.

tangent space as giving another vector of elements of the tangent space as follows:

$$(\mathbf{A}\boldsymbol{\xi})_i := \sum_j \mathbf{A}_{i,j} \xi_j, \quad (33)$$

where  $\xi_j$  means the  $j$ th component of  $\boldsymbol{\xi}$ .

The control loop is as follows.

- (1) Obtain the requested end effector position  $\eta_r$ , and compute the requested acceleration

$$\alpha_r = \ddot{\eta}_r. \quad (34)$$

- (2) Measure actuator values  $\boldsymbol{\ell}$ .
- (3) Calculate the actual end effector position:

$$\boldsymbol{\eta} = \mathbf{Y}(\boldsymbol{\ell}). \quad (35)$$

- (4) Find the  $\Delta$  difference between the actual end effector position and the requested end effector position:

$$\boldsymbol{\theta}_d = \Delta(\boldsymbol{\eta}, \boldsymbol{\eta}_r) \quad (36)$$

and compute the vector of derivatives

$$\boldsymbol{\theta}_d = [\boldsymbol{\theta}_d, \dot{\boldsymbol{\theta}}_d, \ddot{\boldsymbol{\theta}}_d, \dots, \boldsymbol{\theta}_d^{(l-1)}]^T. \quad (37)$$

- (5) Calculate the command end effector acceleration:

$$\dot{\boldsymbol{\xi}} = \mathbf{A}\boldsymbol{\xi} + \mathbf{B}\boldsymbol{\theta}_d \quad (38)$$

$$\alpha_c = \alpha_r + \mathbf{C}\boldsymbol{\xi} + \mathbf{D}\boldsymbol{\theta}_d. \quad (39)$$

- (6) Determine the command end effector force to be applied to the end effector:

$$\boldsymbol{\tau}_c = \boldsymbol{\mu} + \mathbf{M}\alpha_c. \quad (40)$$

- (7) Calculate the requested rate of change of the lengths of the cables

$$\dot{\boldsymbol{\ell}}_r = \boldsymbol{\Lambda}(\boldsymbol{\eta}_r)\boldsymbol{\varphi}_r, \quad (41)$$

and find the resistance overcoming part of the command force for the actuators

$$\boldsymbol{f}_b = k_0 \dot{\boldsymbol{\ell}}_r. \quad (42)$$

- (8) Use equation (15) to calculate the no-load actuator forces.

$$\boldsymbol{f}_0 = m_0 \boldsymbol{\Lambda}_\eta \boldsymbol{\alpha} + m_0 \boldsymbol{\varphi} \cdot \frac{d\boldsymbol{\Lambda}_\eta}{d\boldsymbol{\eta}} \boldsymbol{\varphi}. \quad (43)$$

- (9) Determine whether  $(\boldsymbol{\tau}_c, \boldsymbol{f}_b, \boldsymbol{f}_0) \in \mathcal{W}$ . If it is, calculate part of the actuator forces using

$$\boldsymbol{f}_p = \mathbf{F}(\boldsymbol{\tau}_c, \boldsymbol{f}_b, \boldsymbol{f}_0), \quad (44)$$

and command the actuators with

$$\boldsymbol{f}_c = \boldsymbol{f}_p + \boldsymbol{f}_b. \quad (45)$$

Otherwise, declare that the end effector is out of its workspace, command the actuators to brake, and quit.

- (10) Go back to Step 1.

Note that in Steps 6, 8, and 9, the quantities  $\mathbf{M}$ ,  $\boldsymbol{\mu}$ ,  $\boldsymbol{\Lambda}$ ,  $\mathcal{W}$ , and  $\mathbf{F}$  are calculated from  $\boldsymbol{\eta}$  and  $\boldsymbol{\varphi}$ , but they could just as well be calculated from  $\boldsymbol{\eta}_r$  and  $\boldsymbol{\varphi}_r$ , the only change required being to equation (36) to

$$\boldsymbol{\theta}_d = -\Delta(\boldsymbol{\eta}_r, \boldsymbol{\eta}) \quad (46)$$

The algorithm is shown as a block diagram in Figure 1.

## 5. THEORETICAL JUSTIFICATION FOR THE ROBOT CONTROLLER

**Assumption 1.** *The interaction between the command force  $f_c$ , the actual force  $f$ , and the actuator value  $\ell$  of a single actuator, is given by the linear system*

$$\begin{aligned} f + c_2 \dot{f} + \dots + c_n f^{(n-1)} \\ + k_0 \dot{\ell} + k_1 \ddot{\ell} + \dots + k_n \ell^{(n+1)} \\ = f_c + \tilde{c}_2 \dot{f}_c + \dots + \tilde{c}_p f_c^{(p-1)}. \end{aligned} \quad (47)$$

Note this linearity can be difficult to achieve if friction is significant in the actuators. Friction is highly non-linear, especially when  $\dot{\ell}$  and  $f$  switch between having the same sign and having different signs, as could happen with an active load.

If the actuator has a passive load  $m$  as described in Section 3, then equation (47) becomes

$$\begin{aligned} \ddot{\ell} + c_2 \ell^{(3)} + \dots + c_n \ell^{(n+1)} \\ + \frac{k_0}{m} \dot{\ell} + \frac{k_1}{m} \ddot{\ell} + \dots + \frac{k_n}{m} \ell^{(n+1)} \\ = a_c + \tilde{c}_2 \dot{a}_c + \dots + \tilde{c}_p a_c^{(p-1)}. \end{aligned} \quad (48)$$

The original open-loop controller was derived from the assumption that equation (47) is a perfect description of the passively loaded actuator:

$$\begin{aligned} f_c + \tilde{c}_2 \dot{f}_c + \dots + \tilde{c}_p f_c^{(p-1)} \\ = m(\ddot{\ell}_r + c_2 \ell_r^{(3)} + \dots + c_n \ell_r^{(n+1)}) \\ + k_0 \dot{\ell}_r + k_1 \ddot{\ell}_r + \dots + k_n \ell_r^{(n+1)}, \end{aligned} \quad (49)$$

which in Section 3 was approximated with equation (23).

**Assumption 2.** *For every  $m \in [m_0, \infty]$ , equations (29), (30), (31) and (32) provide a good closed-loop feed-forward controller for system (48).*

This assumption can either be tested theoretically using eigenvalue analysis, or experimentally by loading various passive loads onto a single actuator. The latter approach doesn't require any knowledge of the coefficients in equation (47). We simply need to believe that such an equation exists.

**Assumption 3.** *The time scale of the corrections  $\theta_d$  is much smaller than the time change of  $\eta_r$ , and the magnitude of  $\theta_d$  and its derivatives are much smaller than that of  $\eta$  and its corresponding derivatives. This means we can assume that the time derivatives of  $\eta$  are negligible compared to  $\eta$ , and hence we can assume the matrices  $\mathbf{M}$ ,  $\mathbf{F}$ , and the covector  $\mu$ , and their derivatives, are constant in the time scales in which the controller operates. We also assume that equation (20) holds for time derivatives of both sides,*

*and that the constants are uniformly controlled in the ranges achieved.*

The main result of this paper, which we state below, is described as an 'assertion' rather than a 'theorem,' as the proofs are not very rigorous.

**Assertion 1.** *Given Assumptions 1, 2, and 3, the algorithm described in Section 4 is a good controller for the parallel actuator driven robot.*

Pick a time  $t_0$  which is in the range of times in which the controller performs the required corrections. Let  $\eta_0 = \eta(t_0)$ . Define

$$\theta = \Delta(\eta, \eta_0) \quad (50)$$

$$\theta_r = \Delta(\eta_r, \eta_0). \quad (51)$$

Thus

$$\eta \approx \eta_0 + \theta \quad (52)$$

$$\eta_r \approx \eta_0 + \theta_r, \quad (53)$$

and if we set

$$\varphi_r = \dot{\eta} \quad (54)$$

then

$$\varphi \approx \dot{\theta} \quad (55)$$

$$\varphi_r \approx \dot{\theta}_r, \quad (56)$$

and we have

$$\theta_d \approx \theta - \theta_r. \quad (57)$$

Let  $n_{\mathcal{M}}$  be the dimension of  $\mathcal{M}$ , and define the  $(n_{\mathcal{M}} \times n_{\mathcal{M}})$  matrix

$$\mathbf{N} = \mathbf{M}^{-1} \Lambda^T \Lambda. \quad (58)$$

**Assertion 2.** *With the same assumptions as Assertion 1, if the end effector is controlled by the algorithm given in Section 4, then we have*

$$\begin{aligned} \ddot{\theta} + c_2 \theta^{(3)} + \dots + c_n \theta^{(n+1)} \\ + \mathbf{N}(k_0 \dot{\theta} + k_1 \ddot{\theta} + \dots + k_n \theta^{(n+1)}) \\ \approx \alpha_c + \tilde{c}_2 \dot{\alpha}_c + \dots + \tilde{c}_p \alpha_c^{(p-1)} \end{aligned} \quad (59)$$

where

$$\alpha_c \approx \hat{\alpha}_c + k_0 \mathbf{N} \dot{\theta}_r \quad (60)$$

and  $\hat{\alpha}_c$  is calculated thus:

$$\boldsymbol{\theta}_d = [\theta_d, \dot{\theta}_d, \ddot{\theta}_d, \dots, \theta_d^{(l-1)}]^T \quad (61)$$

$$\dot{\boldsymbol{\xi}} = \mathbf{A}\boldsymbol{\xi} + \mathbf{B}\theta_d \quad (62)$$

$$\hat{\alpha}_c = \alpha_r + \mathbf{C}\boldsymbol{\xi} + \mathbf{D}\theta_d. \quad (63)$$

*Proof.* Rewrite equation (47) for the  $j$ th actuator:

$$\begin{aligned} f_j + c_2 \dot{f}_j + \dots + c_n f_j^{(n-1)} \\ + k_0 \dot{\ell}_j + k_1 \ddot{\ell}_j + \dots + k_n \ell_j^{(n+1)} \\ = f_{c,j} + \tilde{c}_2 \dot{f}_{c,j} + \dots + \tilde{c}_p f_{c,j}^{(p-1)}. \end{aligned} \quad (64)$$

From equations (4), (42), (44), (45), and (56), we obtain

$$f_{c,j} = F_j(\tau_c, \bar{\mathbf{f}}_c) + k_0 \Lambda \dot{\theta}, \quad (65)$$

and applying  $\mathbf{T} = \Lambda^T$  we obtain

$$\mathbf{T} \mathbf{f}_c = \tau_c + k_0 \Lambda^T \Lambda \dot{\theta}_r. \quad (66)$$

Similarly, from equations (4) and (55), we have

$$\mathbf{T} \mathbf{f} = \tau, \quad (67)$$

where  $\tau$  is the actual end effector force, and

$$\mathbf{T} \dot{\ell} = \Lambda^T \Lambda \dot{\theta}. \quad (68)$$

Hence from Assumption 3, we obtain

$$\begin{aligned} \tau + c_2 \dot{\tau} + \dots + c_n \tau^{(n-1)} \\ + \Lambda^T \Lambda (k_0 \dot{\theta} + k_1 \ddot{\theta} + \dots + k_n \theta^{(n+1)}) \\ \approx \tau_c + k_0 \Lambda^T \Lambda \dot{\theta}_r + \tilde{c}_2 (\dot{\tau}_c + k_0 \Lambda^T \Lambda \ddot{\theta}_r) \\ + \dots + \tilde{c}_p (\tau_c^{(p-1)} + k_0 \Lambda^T \Lambda \theta_r^{(p)}). \end{aligned} \quad (69)$$

Next, subtracting  $\mu$ , and then left multiplying by  $\mathbf{M}^{-1}$ , and using Assumption 3 again, we obtain equation (59). The rest of the assertion follows by equation (57).  $\square$

**Lemma 1.** *The matrix  $\mathbf{N}$  has a basis of eigenvectors, with eigenvalues in  $[0, m_0^{-1}]$ .*

*Proof.* Let

$$\tilde{\mathbf{N}} = \mathbf{M}^{-1/2} \Lambda^T \Lambda \mathbf{M}^{-1/2}. \quad (70)$$

Clearly  $\tilde{\mathbf{N}}$  is symmetric and positive semi-definite, and since  $\mathbf{M} - m_0 \Lambda^T \Lambda$  is positive definite, we have

$$m_0^{-1} \mathbf{I} - \tilde{\mathbf{N}} = m_0^{-1} \mathbf{M}^{-1/2} (\mathbf{M} - m_0 \Lambda^T \Lambda) \mathbf{M}^{-1/2} \quad (71)$$

is positive definite. (Here  $\mathbf{I}$  denotes the  $(n_{\mathcal{M}} \times n_{\mathcal{M}})$  identity matrix.) Hence  $\tilde{\mathbf{N}}$  has a basis of eigenvectors, with eigenvalues in  $[0, m_0^{-1}]$ . Also,

$$\mathbf{N} = \mathbf{M}^{-1/2} \tilde{\mathbf{N}} \mathbf{M}^{1/2}, \quad (72)$$

and hence  $\mathbf{N}$  and  $\tilde{\mathbf{N}}$  are similar matrices.  $\square$

*Proof of Assertion 1.* We use Lemma 1 to obtain  $\sigma_1, \sigma_2, \dots, \sigma_{n_{\mathcal{M}}}$  a basis of eigenvectors of  $\mathbf{N}$ , with corresponding eigenvalues  $m_1^{-1}, m_2^{-1}, \dots, m_{n_{\mathcal{M}}}^{-1}$ , where  $m_1, m_2, \dots, m_{n_{\mathcal{M}}} \in [m_0, \infty]$ . We also form a dual basis  $\pi_1, \pi_2, \dots, \pi_{n_{\mathcal{M}}}$  that satisfies

$$\sigma_i \cdot \pi_j = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j, \end{cases} \quad (73)$$

so that for any  $\psi \in \mathbb{R}^{n_{\mathcal{M}}}$  we have

$$\psi = \sum_{i=1}^{n_{\mathcal{M}}} (\psi \cdot \pi_i) \sigma_i \quad (74)$$

$$\pi_i \cdot \mathbf{N} \beta = m_i^{-1} (\pi_i \cdot \beta). \quad (75)$$

By Assumption 3, we can assume that all these vectors and eigenvalues are constant. For each  $1 \leq i \leq n_{\mathcal{M}}$ , dot product the equations in Assertion 2 by  $\pi_i$ . Then it may be seen that the resulting equations satisfy the hypotheses of Assumption 2, with  $y$  replaced by  $\theta \cdot \pi_i$ , with  $y_r$  replaced by  $\theta_r \cdot \pi_i$ , and with  $m$  replaced by  $m_i$ . Thus  $\theta \cdot \pi_i$  is well controlled by  $\theta_r \cdot \pi_i$ .

Then it follows by equation (74) that  $\theta$  is well controlled by  $\theta_r$ . Therefore by equations (52) and (53), we have that  $\eta$  is well controlled by  $\eta_r$ .  $\square$
